

# Different ways of estimating the GGTO, and their impact on the position accuracy

P. Defraigne , Royal Observatory of Belgium  
I. Sesia, T.T. Thai, G. Signorile, INRIM  
P. Tavella, BIPM

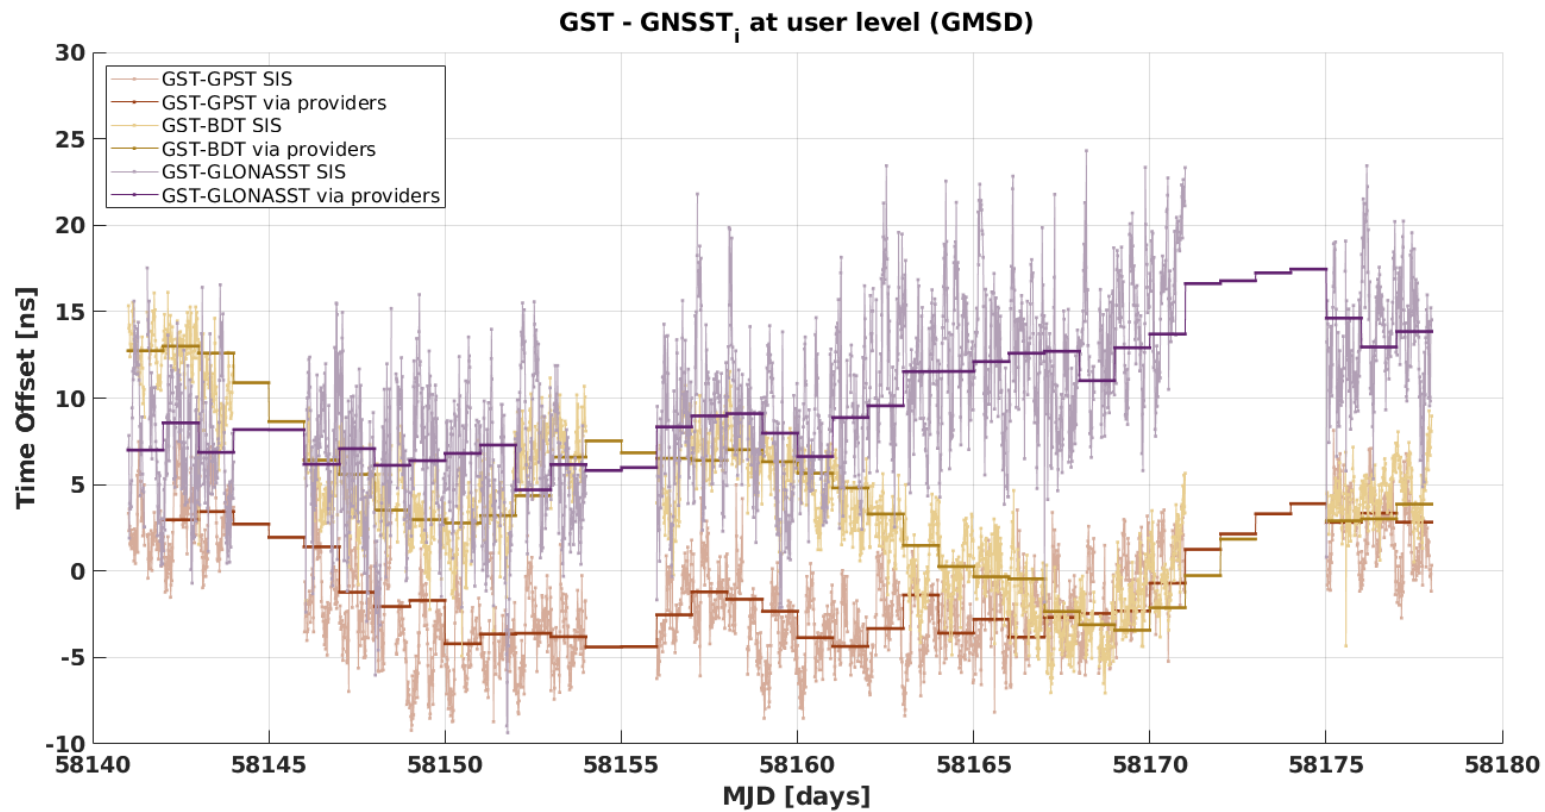

# Outline

- Proposed ways of unifying the XYTO dissemination and their performances
  - Using an average of GNSS Time scales as reference
  - Using the  $UTC_{pred}$  as reference
- Which is the needed XYTO accuracy for positioning?
  - When should the XYTO be determined or taken from nav message
  - Impact of XYTO errors on the position error
- Conclusions

# CASE 1: broadcast $\text{GNSST}_i - \text{GNSST}_{\text{mean}}$

# Efficiency of GXTO as broadcast against $\text{GNSS}_{\text{mean}}$

# CASE 1: conclusion

- $\text{GNSST}_i - \text{GNSST}_{\text{mean}}$  provides an accurate access to XYTO for the user
- What matters most is:

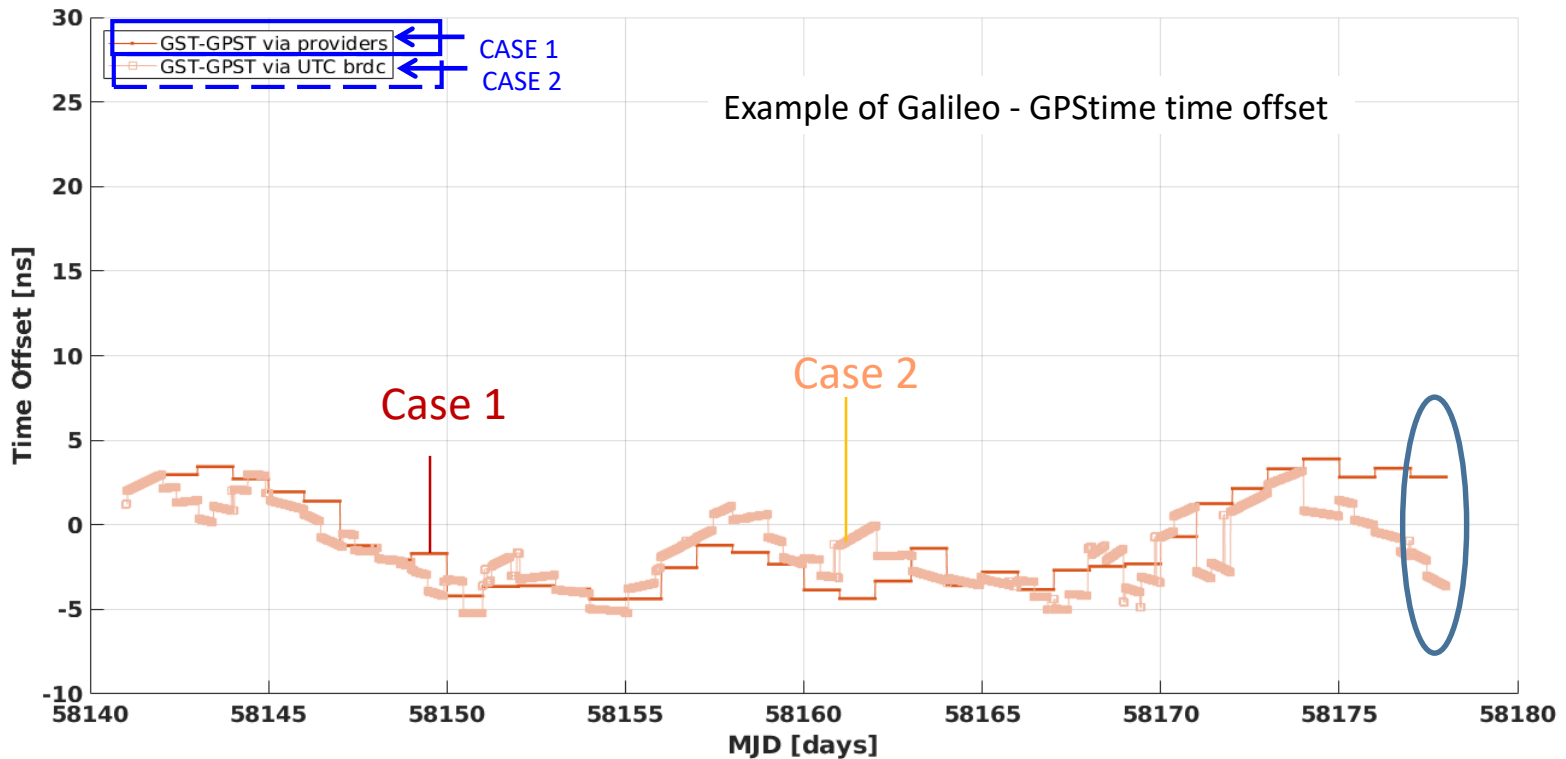

Not the different visibility of satellites

but the calibration of each GNSS provider Rx is fundamental as residual bias of about 5 ns are often observed

# CASE 2: XYTO via broadcast $UTC_{pred} - GNSST$

$$XYTO = [GNSST_x - \cancel{UTC_{brdc}}_x] - [GNSST_y - \cancel{UTC_{brdc}}_y]$$

Difference can be several ns (or more)

# Conclusion on CASE1/CASE2

- CASE 1 XYTO, assuming all systems brdc GNSSTi-GNSSTmean
- CASE 2 XYTO, based on Brdc UTC-GNSSTi prediction in the Navigation Messages

	accuracy	System level
GNSST <sub>mean</sub>	5 ns	Need for calibrated receiver and algorithm (same as current GGTO by Galileo)
UTC <sub>pred</sub> (brdc)	10 (20?) ns	Nothing – except maintaining UTC <sub>pred</sub> close to UTC

# Which is the needed XYTO accuracy?

- $GGTO = GPST - GST$

But in the receiver :

$$GPST^{\circledR} = GPST + \text{HW delays (signal used)}$$

$$GST^{\circledR} = GST + \text{HW delays (signal used)}$$

$$GGTO = GPST^{\circledR} - GST^{\circledR} - \text{HWD(GPS)} + \text{HWD(Galileo)}$$

- **Single Frequency users :**

(L1) is used by both systems,

we can consider that the HWD is close (difference < 3ns)

BUT SF users need TGD and BGD, while there is a bias of about 2 ns in the broadcast BGD → difference between the true GGTO and the GGTO(user) is within 5 ns.

# Which is the needed XYTO accuracy?

- $GGTO = GPST - GST$

But in the receiver :

$$GPST^{\circledR} = GPST + \text{HW delays (signal used)}$$

$$GST^{\circledR} = GST + \text{HW delays (signal used)}$$

$$GGTO = GPST^{\circledR} - GST^{\circledR} - \text{HWD(GPS)} + \text{HWD(Galileo)}$$

- **Dual-Frequency users:**

(L1 L2) is used by GPS, (L1 L5) by Galileo,

HW delays of the IF combination can be up to 10 ns.

→ Even if an accurate GGTO is broadcast, it can be far from the user GGTO which includes HW biases.

# Impact of XYTO accuracy on positioning

- Use GPS+Galileo data and GGTO
- Station in Brussels with good visibility
- Single-Frequency user, Klobuchar for the iono correction
- Compare position obtained when estimating the GGTO using brdc GGTO, with errors between 0 and 20 ns
- Simulate canyons using different elevation cutoffs
- Each epoch, determine position with available satellites

# Horizontal Position error over time

No elevation cutoff

Correct GGTO (for the receiver)

GGTO "error" 7 ns

# Horizontal Position error over time

Cutoff  $30^\circ$

Correct GGTO (for the receiver)

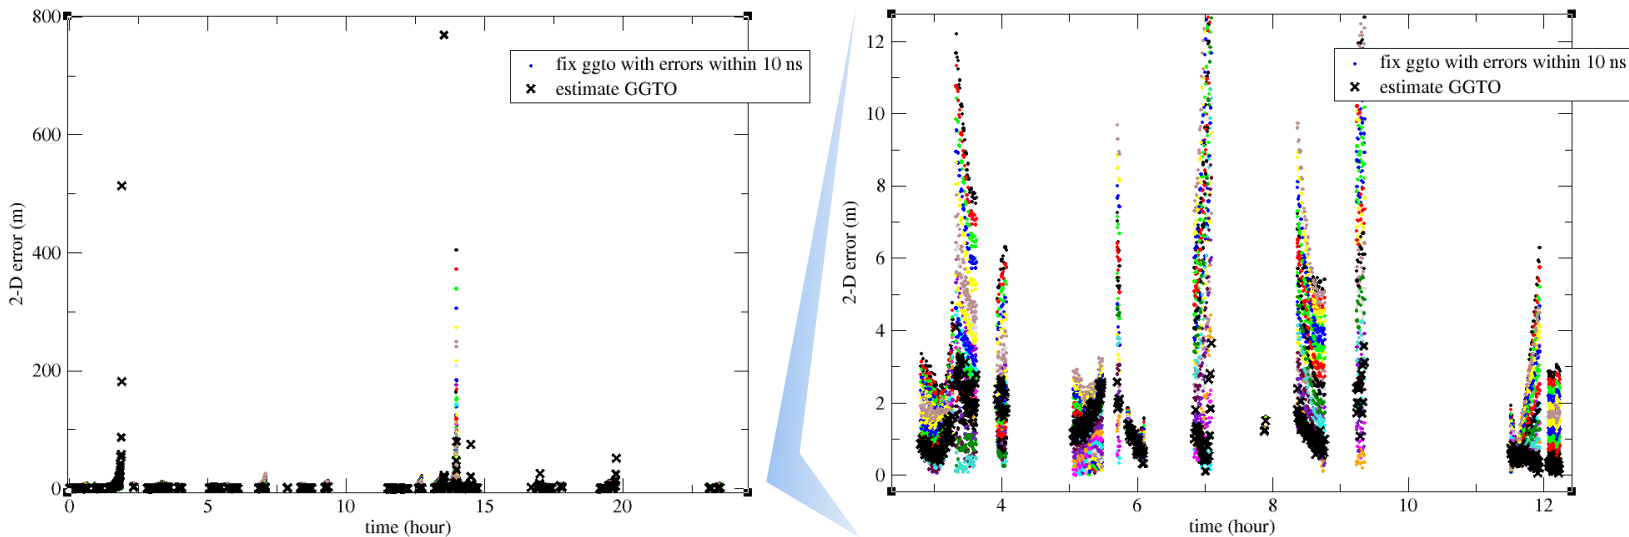

GGTO error 7 ns

Note : the “correct GGTO” depends on the errors in brdc satellite clocks  $\rightarrow$  more sensitive when there are less satellites

# When only 5 satellites available

(here in a cutoff at 50°)

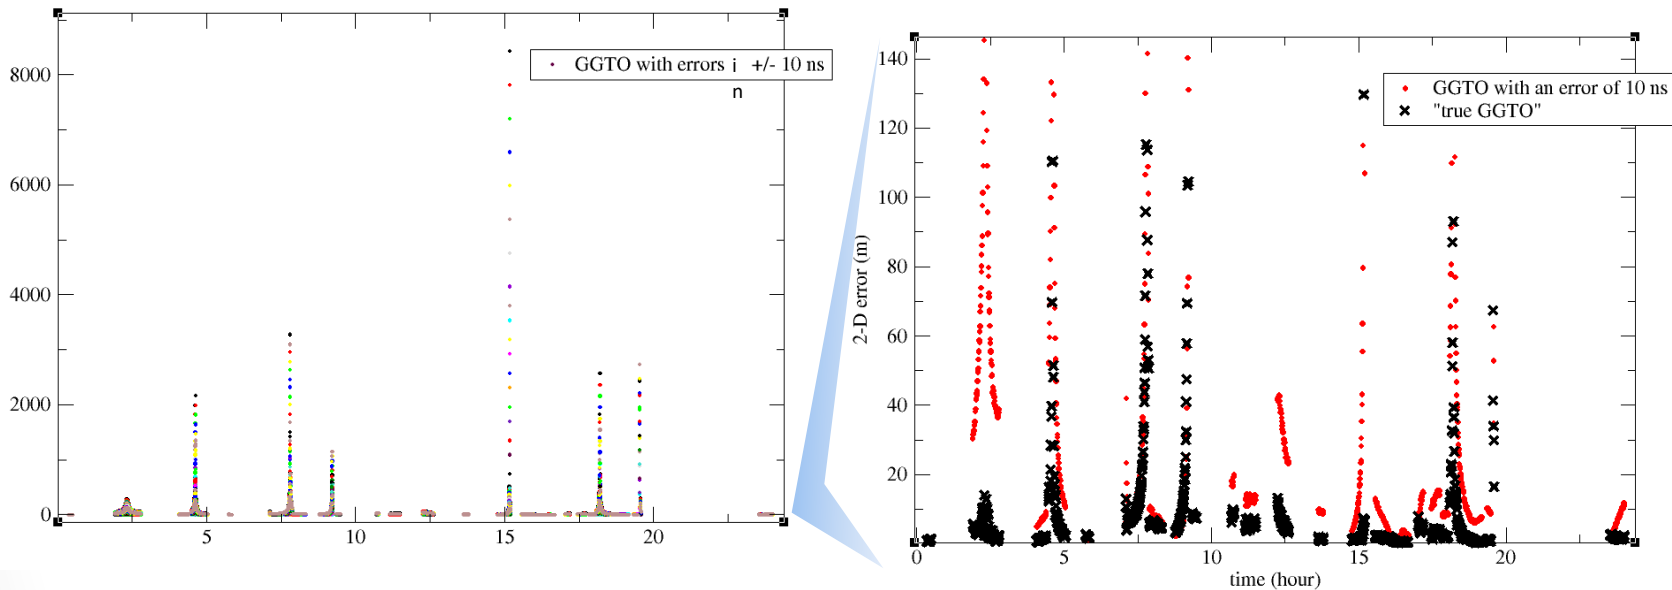

- Estimate GGTO is generally better,
- furthermore, not always the same ‘fixed’ GGTO gives the best solution.
- **Conclusion :**  
**determine GGTO as soon as possible, even with 5 satellites**

# When only 4 satellites available

→ GGTO mandatory

Results here for cutoff  $50^\circ$

At all these epochs, we would not have a solution with only one constellation

- With 4 satellites like in a canyon, having a “correct GGTO” improves the position accuracy
- Even with a “correct GGTO”, the position error can be large ( $>200\text{m}$ ), due to geometry + few satellites
- An error of 10 ns induces horizontal error  $> 100\text{ m}$  for only 6.5% of time while 2.0% with a “correct GGTO”

# How getting the “correct GGTO”?

Correct GGTO = GPST-GST-HW(receiver)

- From Nav message → uncertainty of several ns.
- From a previous estimation : uncertainty depends on the time elapsed since the last estimation in view of
  - the stability of the GNSST
  - the stability of the HW delay

# Conclusion (1/2)

- A correct XYTO at receiver level is always different from the broadcast value due to inter-system hardware delays (can be large especially for different frequencies)
- Broadcast values of XYTO should be used only when the number of satellites available prevents its determination
- When not enough satellites are available to determine a YXTO, a fixed value should be used, either from a previous estimation by the receiver (the best) or from the navigation message
- In that case, horizontal position errors can be large even with the correct GGTO (> 200m),

# Conclusion (2/2)

- The accuracy needed on the broadcast XYTO should be based on the expected position accuracy in canyons,  
Example : for 100 m horizontal, we got
  - 98.0 % of the time (with 4 sat) for the “correct GGTO”
  - 93.5 % of the time (with 4 sat) for an error of 10 ns (which is expected as the range of error due to HW delays of the receiver)
- So, if an uncertainty of 10 ns is accepted on the XYTO, then using GNSST-UTC<sub>pred</sub> broadcast in the nav message will be sufficient, as soon as the UTC<sub>pred</sub> coincide within 10 ns
